45

46 Abstract

47 Two different beers, a Special beer (5.5 % ABV) and a Reserve beer (6.5% ABV) were
48 pervaporated in order to recover aromas to be added to a low-alcohol beer (less than 1% ABV)
49 and an alcohol-free beer (less than 0.1% ABV) to improve their sensory quality. Sensory
50 analysis confirmed that this was accomplished.

51 Through the pervaporation process, three flavor constituents of beer (isobutyl alcohol, ethyl
52 acetate and isoamyl acetate) were analyzed in detail. Selectivities were roughly predicted by
53 an easy model based on the Hildebrand solubility parameters for the polymer and the species
54 in the solution. According to the model, a polymer will transmit a species almost perfectly if
55 their solubility parameters coincide.

56 This model helps to calculate the relative selectivities from solubility parameters and can
57 provide guidance when choosing the membrane for specific separation requirements in food
58 processing or other separation problems where pervaporation can be of great help.

68

69 **1. Introduction**

70 Beer is obtained by the brewing and fermentation of starch (mainly derived from malted
71 barley) germinated in water in the presence of yeast. It is a traditional beverage and closely
72 linked to the Mediterranean culture (Olaniran et al., 2011). Recent studies have demonstrated
73 that a moderate consumption of beer produces beneficial effects on health (Nascentes et al.,
74 2005).

75 Non-alcohol beer is a beer with very low or no alcohol content. Depending on legal regulations
76 in different countries, the required alcohol by volume (ABV) maximum thresholds are diverse.
77 In most of the EU countries beers with low alcohol content are divided into alcohol free beers,
78 less than or equal to 0.5% ABV, and low-alcohol beers with no more than 1.2% ABV. However,
79 in the United States alcohol-free beer means that there is no alcohol present, while 0.5% ABV
80 corresponds to the upper limit of so-called non-alcoholic beer or “near-beer” (Brányik et al.,
81 2012).

82 The market of non-alcoholic brews has improved over the last five to ten years, mainly
83 because new driving/drinking rules, a healthier lifestyle and religious reasons. However,
84 alcohol-free and low-alcohol beers markedly differ in taste and flavor from regular beer. This
85 stems from a lack of flavor due to the elimination of ethanol and other alcohols, some
86 favorable compounds are missing because ethanol operates as a solvent and the risk of non-
87 alcohol beer contamination with spoilage microorganisms increases as a result of the lack of
88 ethanol (Blanco et al., 2013). Therefore, it becomes important to bring the flavor of non-
89 alcoholic beverages into line with that of their typical alcoholic counterparts. Despite recent
90 developments, there still seems to be a gap in the market waiting to be filled.

91 Habitual non-alcoholic brews, such as beer or wine, are produced by arresting fermentation.
92 During fermentation, yeasts produce by-products, such as higher alcohols and esters, making a
93 great contribution to the aroma and taste of the brew. If the fermentation is interrupted, the
94 flavor of the non-alcoholic brew does not improve unto the typical flavor of the alcoholic
95 brews (Kunze, 1999). There are other processes for producing non-alcoholic beverages, by
96 restricting the ethanol fermentation, such as the use of special or immobilized yeasts as well as
97 the use of low sugar raw materials (Lewis and Young, 1995; Pickering, 2000).

98 Alternatively, non-alcoholic beverages can be produced by removing the ethanol from a
99 completely fermented beverage. The most common separation techniques for beverage
100 dealcoholization are heat treatment or membrane-based processes (Catarino et al., 2007).
101 Heat treatment processes include evaporation and distillation or vapor stripping, in both cases
102 under vacuum conditions (Gómez-Plaza et al., 1999; Belisario et al., 2009). Membrane-based
103 processes include reverse osmosis (Labanda et al., 2009; López et al., 2005; Pilipovik and
104 Riverol, 2005), nanofiltration (Verhoef et al., 2008), dialysis (Petkovska et al., 1997; Leskosek et
105 al., 1997) and pervaporation (Takacs et al., 2007).

106 Pervaporation is a process used to separate one or more compounds in a liquid using
107 semipermeable membranes in which the permeate exits as vapor in the low pressure

108 permeate side where there is vacuum, while the material retained remains as liquid (Feng and
109 Huang, 1997; Kimmerle and Gudernatsch, 1991). Permeate which is in vapor phase is then
110 condensed and would be reintroduced into the final product. The retentate keeps other
111 components and may be used by other process or recycled for further separation.

112 Pervaporation is one of the most effective membrane processes for aroma recovery in
113 beverages. Pervaporation membranes are very selective for several chemical groups important
114 in the aroma profiles of beverages (Shepherd et al., 2002; Sampranpiboon et al., 2000; Baudot
115 et al., 1999; Dobrak et al., 2010). During the last years, pervaporation has been successfully
116 applied for recovering aroma compounds from fruit juices (Figoli et al., 2009, Raisi and
117 Aroujalian, 2011; Pereira et al., 2002; Karlsson and Tragardh, 1997; Borjesson et al., 1996) for
118 subsequent addition to the same juice, after concentration by evaporation (Karlsson and
119 Tragardh, 1996; She and Hwang, 2006; García et al., 2008). Pervaporation has been also
120 applied, over the last few years, for ethanol removal (Verhoef et al., 2008; Takacs et al., 2007)
121 and aroma recovery from alcoholic beverages (Karlsson et al., 1996; Brazinha and Crespo,
122 2009). It has also been used in wine dealcoholization (Catarino and Mendes, 2011a). This
123 method has been used too in the process of developing non-alcohol beer (Kimmerle and
124 Gudernatsch, 1991).

125 Catarino tried to extract and analyze seven aromatic compounds characterizing the profile of a
126 beer by pervaporation (Catarino M. et al., 2009). The compounds analyzed were four
127 alcohols (ethanol, propanol, isobutanol and isoamyl alcohol), two esters (ethyl acetate
128 and isoamyl acetate) and an aldehyde (acetaldehyde). The ratio alcohol/ester increases with
129 increasing temperature and decreases with the feed rate and pressure (Catarino M. et al.,
130 2009).

131 In 2010 Catarino produced non-alcohol beer extracting firstly the aromas by pervaporation
132 using POMS/PEI type membranes and then proceeding to dealcoholization by spinning cone
133 column distillation (SCC); the extracted aroma was reincorporated and subsequently both the
134 quality of the aroma and productivity of the process were assessed (Catarino and
135 Mendes, 2011b).

136 Pervaporation represents an alternative to the conventional separation processes, such as,
137 steam distillation, liquid solvent extraction and vacuum distillation. Their energy consumption
138 is normally lower and there is no need of chemical additives. Besides, they can be operated at
139 low temperatures, which is essential when sensitive aroma compounds are intended to be
140 separated (Pereira et al., 2005; Bluemke and Schrader, 2001; Raisi et al., 2008).

141 The aim of this work was to develop a non-alcoholic beer recovering flavors from regular beers
142 by pervaporation and incorporating them later to non-alcoholic beer.

143

144 **1.1 Theory**

145 The flux of matter of an i-species through a pervaporation membrane can be described by a
146 solution-diffusion model (Lonsdale et al., 1965):

$$147 \quad J_i = \frac{D_{i,m} S_i^{\text{mass}}}{\Delta x} \frac{\rho_{\text{polymer}}}{M_{\text{polymer}}} w_{i,\text{feed}} \quad (1)$$

148 $D_{i,m}$ is the diffusion coefficient of the i -component in the membrane, S_i^{mass} accounts for the
 149 solubility in terms of its mass fraction in the polymer (for a polymeric membrane). M_{polymer} and
 150 ρ_{polymer} are the molar mass and density of the polymer. Δx is the thickness of the membrane
 151 and $w_{i,\text{feed}}$ is the mass fraction of the i -th component in the feed solution. The multiplication of
 152 the diffusion coefficient and the solubility gives the permeability:

$$153 \quad P_i = D_{i,m} S_i^{\text{mass}} \quad (2)$$

154 Equation (1) can be obtained from Fick's first law, by assuming small concentration gradients
 155 through the membrane, diluted solutions and a negligible partial pressure of all components in
 156 the permeate side (downstream). In terms of these relationships the key factors to estimate
 157 the flux are its diffusivity and solubility for a given membrane.

158 According to the Flory-Huggins theory, the activity of the solvent can be evaluated by
 159 (Prausnitz et al., 1999):

$$160 \quad \ln a_i = \ln \phi_i + \left(1 + \frac{v_i}{v_p} \right) \phi_p + \chi_i \phi_p^2 \quad (3)$$

161 Where a_i , ϕ_i and v_i are the activity, the volume fraction and the molar volume of the i -th species
 162 respectively. χ is the Flory Huggins interaction parameter, and it depends on the
 163 intermolecular forces between the polymer chain and the solvent.

164 According to the Scatchard-Hildebrand model, χ would be:

$$165 \quad \chi_i = \frac{v_i}{RT} (\delta_i - \delta_p)^2 \quad (4)$$

166 Where R is the gas constant, T the absolute temperature, and, δ_i and δ_p are the Hildebrand
 167 solubility parameter of the i -th component and of the polymer respectively. The Hildebrand
 168 solubility parameters, δ , can be evaluated (Niemistö et al., 2013) from the Hansen dispersion
 169 parameter, δ^d , the Hansen polarity parameter, δ^p , and the Hansen hydrogen-bonding
 170 parameter, δ^h , as:

$$171 \quad \begin{aligned} (\delta_i - \delta_p)^2 &\equiv \Delta \delta^2 = (\Delta \delta^d)^2 + (\Delta \delta^p)^2 + (\Delta \delta^h)^2 = \\ &= (\delta_i^d - \delta_p^d)^2 + (\delta_i^p - \delta_p^p)^2 + (\delta_i^h - \delta_p^h)^2 \end{aligned} \quad (5)$$

172 As the Flory-Huggins interaction parameter goes to zero, there is an increasing affinity within
 173 the polymer and the component of the solution with higher solubility and permeability will
 174 result through the membrane.

175 Frequently, Equation (4) is substituted by:

$$176 \quad \chi_i = \alpha \frac{v_i}{RT} \left[(\delta_i^d - \delta_p^d)^2 + \frac{1}{4} (\delta_i^p - \delta_p^p)^2 + \frac{1}{4} (\delta_i^h - \delta_p^h)^2 \right] \quad (6)$$

177 with $\alpha = 0.6$ as obtained by fitting to a big number of polymers (Lindvig et al., 2002).

178 From Equations (3), (4) or (6) if the Hansen solubility parameters are to be used, the activity in
179 the polymer can be evaluated. Of course from activity by:

$$180 \quad a_i = \gamma_i X_i = \Omega_i S_i^{\text{mass}} \Rightarrow S_i^{\text{mass}} = \frac{a_i}{\Omega_i} \quad (7)$$

181 we can obtain S_i^{mass} as required by equation (2). X_i is the molar fraction of the i -th component
182 in the polymer, γ_i is the activity coefficient based on mole fractions while Ω_i is based on mass
183 fractions. This would lead to approximate results and needs a quite complete knowledge of the
184 thermodynamics of the polymer solution system including Ω_i , ϕ_i , ϕ_p , v_i and v_p .

185 These are some of the limitations of the Flory-Huggins theory:

- 186 • It is based on a lattice model that uses various approximations in the "counting"
- 187 process.
- 188 • It ignores "free volume"
- 189 • It assumes random mixing of chains when calculating the entropy and segments in
- 190 calculating the enthalpy
- 191 • Strictly, it only applies to non-polar molecules
- 192 • It only accounts for combinatorial entropy

193 Fortunately there are semiempirical correlations in literature that allow an easy calculation of
194 solubility if the Hildebrand parameters are known (Reddy et al., 1996).

$$195 \quad S_i^{\text{mass}} = \frac{B}{(\delta_i - \delta_p)^2} = \frac{B}{(\delta_i^d - \delta_p^d)^2 + (\delta_i^p - \delta_p^p)^2 + (\delta_i^h - \delta_p^h)^2} \quad (8)$$

196 B can be calculated for one of the permeants in the polymer with known S_i^{mass} .

197 The diffusivity of the i -th component can be evaluated by:

$$198 \quad D_{i,m} = RTA_D e^{B_D/V_f} \quad (9)$$

199 A_D is a constant accounting for the shape and size of the i -th component. B_D denotes a constant
200 related to the size of the polymeric jumping unit (the free volume necessary in order to allow
201 jumping of the solute), V_f the free volume of the polymer (Frisch and Stern, 1983).

202 The mass concentration enrichment factor for the i -component can be defined as:

$$203 \quad \beta_i = \frac{c_i^{\text{permeate}}}{c_i^{\text{feed}}} \quad (10)$$

204 Where c_i^{permeate} is the mass concentration of i in the permeate, and c_i^{feed} in the feed.

205 The pervaporation selectivity for a pair of components i and j, $\alpha_{i,j}$, corresponds to the ratio of
 206 their enrichment factors:

$$207 \quad \alpha_{i,j} = \frac{\beta_i}{\beta_j} \quad (11)$$

208 For diluted solutions and for very low downstream pressures (Cuusler, 1997):

$$209 \quad \alpha_{i,j} = \frac{P_i H_i}{P_j H_j} \quad (12)$$

210 H_i and H_j are the Henry's constants for the i and j components.

211 Equation (12) can be written according to Equations (2), (8) and (9) as:

$$212 \quad \alpha_{i,j} = \frac{(\delta_j - \delta_p)^2 A_{D,i} H_i}{(\delta_i - \delta_p)^2 A_{D,j} H_j} \quad (13)$$

213 if the constant B of Equation (8) and E_D and V_f of Equation (9) are supposed to depend only on
 214 the polymer.

215 A_D must decrease for molecules of larger sizes and thus can be assumed to be inversely
 216 proportional to the area of the surface of the molecule:

$$217 \quad A_{D,i} = \frac{k}{A_i} \quad (14)$$

218 Because k should depend only on the polymer:

$$219 \quad \alpha_{i,j} = \frac{(\delta_j - \delta_p)^2 A_j H_i}{(\delta_i - \delta_p)^2 A_i H_j} \quad (15)$$

220 Equation (15) predicts selectivities that could be compared with the experimental ones as
 221 obtained from Equation (11).

222

223 **2. Materials and methods**

224 **2.1 Materials**

- 225 • **Membrane:** The membrane used in the work was a hydrophobic membrane
 226 commercialized by Pervatech, (Enter, The Netherlands) with a support of PET
 227 (polyethylene), an intermediate Ultrafiltration membrane of polyimide and a thin layer
 228 of PDMS (poly-di-methyl-siloxane) (tg=130°C) with hydrophobic/organophilic
 229 characteristics which allow a high flow of organic compounds. The thickness of the
 230 PDMS active layer is 1 μm (Van Hecke et al., 2012).

- 231 • Beer: We used four different types of beer, even though all of them are lager beers. A
232 Special beer having 13.10% extract Original Gravity, OG, with 5.5% Alcohol By Volume,
233 ABV, and a Reserve beer, 15.05% extract OG and 6.5% ABV. On the other hand we
234 used a low-alcohol beer (less than 1% ABV) which comes from the Special beer and an
235 alcohol-free beer (less than 0.1% ABV) which comes from the Reserve beer.
- 236 • Reagents: We have used four reagents to make the synthetic solution for the initial
237 experiments: ethanol (96.0%), isobutyl alcohol (99.0%), ethyl acetate (99.5%) and
238 isoamyl acetate (98.0%), all of them from Sigma-Aldrich.

239 Pervaporation system: The experimental device is described in Figure 1. The
240 membrane is in a flat sheet cell which provides a membrane active area $A = 6.6 \cdot 10^{-3}$
241 m^2 . A pump extracts the solution or beer to pervaporate from the thermostated feed
242 tank. This fluid circulates tangentially on the membrane in order to limit the effects of
243 concentration-polarization. Downstream, after the membrane cell, a vacuum pump
244 reduces the pressure down to 1 mbar. The permeate condensates in liquid nitrogen
245 cold traps.

246 Gas chromatography (GC) conditions: The GC system consisted of an Agilent
247 Technologies Chromatograph 7890 A. The injection volume was 1 μl . A Nucleosil
248 column C 18 (250 \times 4.6 mm, 5 μm) was used and the carrier gas was He 34.62 cm/s
249 16.057psi (35°C).

250

251 2.2 Methods

252 Two liters of a synthetic aqueous solution of ethanol (5.0 % v/v) was prepared with three
253 aroma compounds (isobutyl alcohol, 12.67 ppm; ethyl acetate, 16.18 ppm and isoamyl acetate,
254 1.38 ppm). These concentrations are quite similar to those of a typical commercial beer
255 (Catarino et al., 2009). **Although, as will be apparent below, the beers we used here have**
256 **higher concentrations of these species, the separation properties depend only slightly on**
257 **concentration. Actually we performed experiments with concentrations close to 100-fold those**
258 **used here without relevant changes in separation.** These aroma compounds were selected
259 because of their wide range of boiling points, one close to ethanol (78.4 °C at 1 atm.) and the
260 rest much higher (Table 1). They are also very relevant aroma compounds to define the overall
261 aroma of beer (Catarino et al., 2009).

262 This solution was filtered in order to test the membrane and the process to establish optimal
263 conditions for pervaporation and to apply them to beer samples. Each experiment took six
264 hours at least. Samples of permeate were taken at intervals of two hours. These samples were
265 taken in cold traps (Figure 1) where, by using liquid nitrogen, the permeate condensed. Gas
266 Chromatography (GC) was the technique used to analyze the samples. **GC was performed at**
267 **25°C.**

268 $3 \cdot 10^{-5} m^3/s$ was the flow of recirculation through the feed recirculation loop (retentate side).
269 Pressures were 94.7 kPa in the retentate side and 0.1 kPa in the downstream side.
270 Temperatures over 25°C would accelerate pervaporation, but they would also enhance

271 evaporation in the feed and could cause denaturation of beer. Lower temperatures would slow
272 down the process.

273 In preliminary tests, the synthetic solution was pervaporated at different feed pressures
274 without any significant variation of flux. This would discard convective fluxes. Also
275 measurements at 80 °C were performed with fluxes nearly 4 times those at 25°C. This seems
276 to confirm that there is no convection and the solution-diffusion model should be appropriate
277 as used in common literature (Baudot et al., 1999; Borjesson et al., 1996; Dobrak et al., 2010)
278 for this polymer.

279 The flow rate used corresponds to a tangential speed of 1 m/s which allows considering
280 concentration polarization as negligible. The feed pressure is only slightly over the atmospheric
281 pressure and is determined by the recirculation flow rate, while the downstream pressure
282 gives a high enough gradient of concentration through the membrane.

283 Once optimum conditions for the experiment were reached, beer samples were pervaporated.
284 The duration of the tests was equal to those of the preview tests (6 hours), for the Special
285 Beer. In the case of Reserve Beer, each experiment took 8 hours due to its more aromatic
286 character. Samples of permeate were taken every two hours. Samples of feed, retentate and
287 permeate were taken to analyze their content of aroma compounds using GC.

288 We incorporated the recovered permeate into low-alcohol and alcohol-free beers to enrich
289 their flavor. The permeated solution is added into a non-alcoholic beer volume equal to the
290 volume of regular beer used to recover these aromas by pervaporation.

291 After enrichment, we checked by sensory evaluation if the enriched beers were preferred to
292 original non-alcohol beers. Sensory analysis of the beer samples was conducted in the sensory
293 analysis room of the Department of Agricultural and Forest Engineering (Food Technology
294 Area, University of Valladolid). The panel was composed of 10 assessors who had been trained
295 according to the Standard ISO 8586-1:1993 (ISO 8586-1, 1993). The panel evaluated different
296 beers with a wide variety of sensory characteristics as external appearance, smell or olfactory-
297 gustatory sensations. After their training, the panel realized two tests, firstly the enriched
298 sample had to be distinguished from non-enriched samples, and, after this, they had to decide
299 which sample they preferred. The samples were presented to the tasters in glass cups and in
300 single cabins.

301

302 **3. Results and Discussion**

303 In Figure 2 the time evolution of the permeate for both the special and reserve beers and the
304 synthetic solutions are shown. The average fluxes for the two beers are shown as well.

305 For both the beers, the flux is more or less stable. For the Special beer, there is a higher flux at
306 the initial steps of the process probably due to its lower content of substances hindering the
307 transport of aromas. In fact, this beer has a lower free dry matter content than the Reserve
308 beer, as mentioned in section 2.1. The average and final flux are higher for the Reserve beer,
309 which has a larger concentration of volatile compounds than the Special beer.

310 The synthetic solution has similar flux evolution than the special beer possibly because they
311 have similar alcohol contents. Fluxes are slightly lower for the synthetic solution and they
312 decrease after the initial increase because its aroma contents are a lower and the decrease of
313 concentration is significant. A slower decay at long times appears also for the special beer
314 probably due to similar reasons.

315 The consecutive average concentrations for the feed and permeate are shown in Figure 3. The
316 ethanol concentration in the permeate is quite similar for each beer along time. This seems
317 logic because the feed concentration of ethanol is constant for each beer. The average
318 concentration of ethanol in the permeate for the special beer is 3.9 ± 0.8 g/L and 4.3 ± 0.2 g/L for
319 the reserve beer. These data correspond to a very similar enrichment factor of ethanol in both
320 the beers and the synthetic solution; $\beta_{\text{Ethanol}} = 9.9 \pm 0.5$. If the variation of ethanol in the beers is
321 evaluated we obtain 0.11% ABV for the special beer and 0.19% ABV for the reserve one.

322 Generally, recovery of compounds increases in Reserve beer because, as mentioned, Reserve
323 beer is usually more aromatic than Special beer. It is important to appreciate in this figure how
324 the recovered concentration of ethyl acetate decreases in each time slot for both beers. The
325 same holds true for isoamyl acetate. This is due to the decrease of the content of these
326 compounds in the feed with time.

327 From data in Figures 2 and 3, the flux for each aroma can be evaluated as shown in Figure 4.
328 The flux of ethanol is almost constant and higher for the reserve beer as could be expected
329 due to its initial higher alcohol content. The alcohol flux is some orders of magnitude higher
330 than the corresponding flux for the aromas again due to their much slower concentration in
331 the feed. The highest flux corresponds to ethyl acetate for both beers. Initially for all the
332 aromas, and especially for ethyl acetate, there is a strong increase in flux followed by a
333 significant decrease and stabilization. In all cases flux is correlated with the initial
334 concentration of the aroma.

335 To avoid the influence of initial concentration, the mass concentration enrichment factor for
336 each component has been evaluated according to Equation (10). As can be seen in Figure 5,
337 the two most abundant aromas have actually a clear initial over-flux followed by a clear
338 stabilization. Ethyl acetate has the highest enrichment factor, while the other two aromas have
339 much lower enrichment factors and are quite similar for a long period of time in both beers.

340 To understand why enrichment is obtained the membrane-solute interaction has to be taken
341 into account. In our case the appropriate membrane must be hydrophobic in order to prevent
342 the passage of water, the main component of beer by far. The membrane selected showed an
343 ethanol/water selectivity over 15 for aqueous 5 % ethanol solution.

344 This strong hydrophobicity will hinder the transport of other polar species such as ethanol
345 against other less polar substances such as those responsible for the aroma in beer. This is
346 interesting in order to selectively retard the passage of ethanol. The compounds passed
347 through the membrane could then be incorporated into non-alcohol beer without requiring
348 ulterior separations to avoid an undesired increase of alcohol content.

349 A relevant parameter to quantify the membrane-solute interactions is the partition coefficient
350 K_r . It is the ratio of concentrations of each species in non-polar and polar phases. Given that
351 this coefficient has a wide range of variation, a logarithmic scale is conventionally used, $\log K_r$

352 (sometimes it is called log P, here we preferred to use log K_r to avoid possible confusions with
353 permeability). It was previously suggested (Blanco et al., en el 2007) that log K_r is correlated
354 with the molecular surface (Table 1) and with the affinity of this surface to each species. The
355 values obtained for log K_r are shown in Table 1. The compound with a higher log K_r would
356 dissolve better in the organic phase and thus would pervaporate better. As shown in Figure 6
357 the order for log K_r is the same as that based on the solubility parameters. As expected, the
358 polar solubility coefficient was particularly well correlated with log K_r .

359 As mentioned in the theory section, the flux of the flavor substances depends on the feed
360 concentration and their interaction with the membrane that determines their solubility
361 (Equation (8)) and diffusivity (Equation (9)) according to Equation (15). The selectivity can also
362 be evaluated from their mass concentration enrichment factors and Equation (11).

363 In Figure 7, the experimental selectivity (Equation (11)) is shown in relation to that of ethanol
364 in the synthetic solution and in the three beers studied compared to the theoretical selectivity
365 according to Equation (15).

366 **Figure 7 shows the experimental tendency is in accordance with the theoretical one. Of course**
367 **the accordance is far from being accurate as should be if the points in this figure were on the**
368 **plotted bisecting line.** Note there are many factors that have not been taken into account in
369 Equation (15), among them, for example, the interaction solute-solute which would be very
370 different in the three solutions studied. Hence, a perfect accordance could not be expected. In
371 any case, there can be no doubt that such a study can be useful to design and predict
372 performances in order to adopt an appropriate pervaporation procedure **because the trend is**
373 **correctly predicted.**

374 The membrane clearly shows a higher selectivity for ethyl acetate over ethanol. The same is
375 true for **isoamyl acetate** to a lower extent. Nevertheless **its** presence in the permeate is low
376 (Figure 3) due to its low concentration in the feed. **In the figure it can be seen that both the**
377 **esters show a decreasing concentration in the permeate while isobutyl alcohol gives an almost**
378 **constant concentration. Which is due to its low solubility.**

379 It is worth noting that the differences in $\delta_j - \delta_p$ between isobutyl alcohol and ethyl acetate or
380 isoamil acetate show that **it could be less transported due to the contribution of hydrogen**
381 **bonds to solubility** (see δ_i^h in Table 1).

382 Except for the special beer, isobutyl alcohol, exhibits a selectivity below 1. This means that a
383 significant recovering of this aroma would imply an appreciable passage of alcohol to the
384 permeate. Fortunately this is not too important because of its low impact on the flavor of beer
385 and sensations in mouth (also true for other high molecular weight alcohols) (García et al.
386 1994).

387 After adding the aroma compounds recovered by pervaporation from the alcoholic beers into
388 the original low-alcohol and alcohol-free original beers, they were analyzed by Gas
389 Chromatography (GC). Table 2 shows how the concentration of aroma compounds generally
390 increased in both reduced alcohol beers after aroma addition. In the case of isoamyl acetate,
391 its concentration in the beers (with or without alcohol) was so low that addition could not be
392 detected by GC. The increase in the alcohol content of the beers after addition of aromas was
393 also negligible. **This corresponds to the loss of pervaporated beers that was already mentioned**

394 to be 0.11 % for the special beer and 0.19% ABV for the reserve one. These small increases in
395 the alcohol degree keeps the enriched beers between the law requirements mentioned in the
396 introduction.

397 We can also see in Table 2 how the increase in the concentration of aroma compounds is
398 important in both beers. For instance, isobutyl alcohol in alcohol-free beer increases 16.33% in
399 the enriched beer, and ethyl acetate in low-alcohol beer increases 35.72% due to the
400 enrichment of this beer.

401 The increase of aroma compounds in enriched beers, shown in Table 2, has a high impact on
402 the sensorial properties of beers. Sensory evaluation was performed in two tests as mentioned
403 above, informing of a certain improvement in aroma. The preference test, showed that, 90% of
404 tasters preferred enriched low-alcohol beer instead of low-alcohol beer and 80% of tasters
405 preferred enriched alcohol-free beer instead of alcohol-free beer. These results can be
406 interpreted as a relevant improvement in quality of non-alcohol beers due to the addition of
407 the aroma compounds recovered by pervaporation. As can be seen in Table 2, the percentages
408 of the selected aroma compounds in the enriched beers are still far below those in the special
409 and reserve beers, further additions would increase even more the taste of the enriched beers
410 although the percentages reached clearly improve their flavour.

411

412 **4. Conclusions**

413

414 We have demonstrated that pervaporation can be used to recover aroma compounds in beer.
415 The addition of these aroma compounds to more or less de-alcoholized beer enriches their
416 flavor. This increases their appreciation and could be used to meet the quality standards
417 required by the market.

418 The relevance of the polymer of the membrane has been highlighted here. Note that according
419 to Equation (15) a polymer will transmit almost perfectly a species if their solubility parameters
420 coincide. A wise tuning of the polymer (or polymers) with the adequate solubility parameter
421 would allow us to obtain very selective membranes for a given (or several) volatile
422 components. In particular it is clear that similar feed concentrations are recovered to different
423 extents due to their different solubilities.

424 The theoretical approximate calculation of relative selectivities from solubility parameters can
425 help in the design of the process and the selection of the membrane in order to comply with
426 specific separation requirements. A good selection of the membrane material could be the key
427 to reaching higher productivities for aroma recovery in beer and other pervaporation
428 processes.

429

430 **5. Acknowledgements**

431

432 Financial support from Junta de Castilla y León (VA332A12-2) and from “Ministerio de Ciencia e
433 Innovación (MCINN)” (CTQ2009-07666, CTQ2012-31076 and MAT2011-25513) is gratefully
434 acknowledged.

435 The authors would like to express their gratitude to Hijos de Rivera S. A. for supplying the
436 beers used in this study.
