\section*{HIGHLIGHTS}
- Gold nanoparticles and lutetium bisphthalocyanine have been co-deposited using the LB technique.
- Films used as voltammetric sensors provide enhanced responses towards hydroquinone.
- The efficient electrocatalytic properties are due to synergistic effects.

\section*{ABSTRACT}
A synergistic electrocatalytic effect was observed in sensors where two electrocatalytic materials (functionalized gold nanoparticles and lutetium bisphthalocyanine) were co-deposited using the Langmuir–Blodgett technique. Films were prepared using a novel method where water soluble functionalised gold nanoparticles [(11-mercaptopoundecyl)tetra(ethylene glycol)] (SAuNPs) were inserted in floating films of lutetium bisphthalocyanine (LuPc\textsubscript{2}) and dimethylidiotadecyliammonium bromide (DODAB) as the amphiphilic matrix. The formation of stable and homogeneous mixed films was confirmed by \textpi-A isotherms, BAM, UV–vis and Raman spectroscopy, as well as by SEM and TEM microscopy. The synergistic effect towards hydroquinone of the electrodes modified with LuPc\textsubscript{2}–DODAB–SAuNP was characterised by an increase in the intensity of the redox peaks and a reduction of the overpotential. This synergistic electrocatalytic effect arose from the interaction between the SAuNPs and the phthalocyanines that occur in the Langmuir–Blodgett films and from the high surface area provided by the nanostructured films. The sensitivity increased with the amount of LuPc\textsubscript{2} and SAuNPs inserted in the films and limits of detection in the range of 10\textsuperscript{-7} mol L\textsuperscript{-1} were attained.

1. Introduction
Phenolic compounds are a large family of molecules which are widely distributed in plant-derived foods. They have attracted great interest due to their potential health benefits. Polyphenolic compounds also contribute to the organoleptic characteristics of foods and affect their antioxidant capacity [1]. The determination of phenols can be carried out using traditional techniques including spectroscopy, gas or liquid chromatography and electrochemical methods. Oxidation of phenols is feasible at inert electrodes (i.e. metallic or glassy carbon electrodes) [2] and at electrodes chemically modified with a variety of materials and biomaterials [3]. The modification of the electrode surface with nanomaterials has demonstrated to be a good strategy to prepare...
sensing devices [4,5]. For instance, electrodes modified with gold nanoparticles (AuNPs) show unique catalytic properties that depend on the AuNP size and on the nature of the protecting groups. In addition, AuNPs provide a large surface area for the detection of analytes, leading to electrochemical sensors with lower detection limits [6–9].

On the other hand, metallophthalocyanines (MPc) and their sandwich type lanthanide derivatives (LnPc2) have demonstrated to behave as excellent sensing materials for the detection of a variety of compounds due to their well-known electrocatalytic properties, fast electron transfer and electron mediator capabilities [10–18].

The design of hybrid systems combining different electrocatalytic materials is very attractive for the development of electrochemical sensors. Recently, AuNPs and phthalocyanines have been successfully combined at a sensor surface using spin coating [19,20]. However, the applications of these composite AuNP/MPc systems require the development of methods allowing both classes of compounds to be co-immobilised in structures with controlled distribution of the two components [21,22].

The LB technique can be an alternative to produce nanostructured multilayers where two or more compounds are co-deposited in mixed films [23]. The materials used to form the films must fulfil the particular requirements of these techniques. For instance, in classical LB deposition, the film-forming materials must be amphiphilic molecules (insoluble in water but soluble in organic solvents). This means that the AuNPs must be capped (i.e. with thiolate groups) which facilitate the adequate dispersion onto the water subphase [24,25]. In turn, to obtain phthalocyanine multilayer assemblies, it is often necessary to mix the phthalocyanines with amphiphiles such as fatty acids or phospholipids that induce flexibility in the monolayers facilitating the transfer to solid substrates [15,18].

In this work, a new method was developed to co-deposit LB films of phthalocyanines with gold nanoparticles. The method consisted in the insertion of water soluble gold nanoparticles [(11-mercaptoundecyl)tetra(ethylene glycol)] (SAuNP) underneath a floating Langmuir film formed by a phthalocyanine [lutetium (III) bisphthalocyanine] and an amphiphile [dimethylidioctadecylammonium bromide] (DODAB). The insertion of the SAuNPs into the nanostructured LuPc2:DODAB floating film to obtain LuPc2:DODAB/SAuNP films was evaluated using spectroscopic and microscopic techniques. Then, the sensing capabilities of films containing different proportions of LuPc2:DODAB and increasing amounts of SAuNP were studied using cyclic voltammetry. In the present work, we focus the attention on the determination of hydroquinone, an antioxidant belonging to the phenols family commonly found in foods such as teas or wines [26]. The synergistic effect caused by the interaction of two electrocatalytic materials: the SAuNPs and the LuPc2 will be discussed.

2. Materials and methods

The lutetium (III) bisphthalocyaninate (LuPc2) was synthesised and purified in the neutral radical state using a previously published method [27]. (11-Mercaptoundecyl)tetra(ethylene glycol) functionalised gold nanoparticles (SAuNP), dimethyldioctadecylammonium bromide (DODAB), and all the chemicals and solvents were purchased from Sigma–Aldrich and Fluka.

Buffer phosphate 0.01 M (pH 7.0) was prepared mixing sodium phosphate monobasic (purity >99%) and sodium phosphate dibasic (purity 99%) in ultrapure water.

LB films were prepared in a KSV 2000 System Langmuir–Blodgett trough equipped with a Wilhelmy plate to measure the surface pressure vs. mean molecular area (Å²) isotherms.

Films containing LuPc2 and DODAB (LuPc2:DODAB) were prepared by spreading a chloroform solution of the corresponding mixture (10:1), (1:1) or (1:10) (1 × 10⁻⁵ mol L⁻¹) onto a water subphase (ultrapure water–Millipore MilliQ kept at 20°C). Then, the barriers were compressed at a speed of 10 mm min⁻¹ to register the Å² isotherms. At a surface pressure of 35 mN m⁻¹, 20 monolayers were transferred to the solid substrates by Z type deposition with a transfer ratio close to 1.

Films containing SAuNP, DODAB and LuPc2 (LuPc2:DODAB/SAuNP), were prepared from chloroform mixtures LuPc2:DODAB (10:1), (1:1) and (1:10) that were spread onto the water subphase. After evaporation of the solvent, 100 or 500 µL of an aqueous solution of SAuNP (0.02% w/v) were injected drop by drop underneath the air–water interface (before compressing the film) and adsorbed inside the floating monolayer. Floating layers of LuPc2:DODAB/SAuNP were compressed and transferred to solid substrates using the same conditions mentioned in the previous paragraph. 20 monolayers LB films were built by Z type deposition with a transfer ratio close to 1. A scheme of the preparation method is shown in Fig. 1. The complete list of the sensors prepared is collected in Table 1.

Langmuir films were analysed with Brewster Angle Microscopy (BAM) using a KSV MicroBAM. UV–vis absorption measurements were conducted using a Shimadzu spectrophotometer UV-1603. TEM images were recorded using a JEM-FS2200 HRIP instrument.

Raman analysis was performed in a Raman spectrometer UV-HR Lab Ram from Horiba–Jobin Yvon, equipped with a LN2-cooled charge-coupled device (CCD) detector. The excitation was carried out with different lasers, including an Nd–YAG laser (emitting at 532 nm) and a He–Ne laser (emitting at 633 nm), with a spectral resolution of 1 cm⁻¹. The sample was excited through the 50× optical objective of a Leica microscope. The scattered light was collected through the same optical objective (back-scattering configuration) with ca. 1 µm spatial resolution.

3. Results and discussion

3.1. Langmuir monolayers

The $\pi$-A isotherms of mixtures of LuPc$_2$:DODAB (proportions 10:11:1 and 1:10) were registered by spreading the corresponding chloroform mixture onto the water subphase and compressing the barriers at a speed of 10 mm min$^{-1}$ while registering the variations of the surface pressure (Fig. 2, top). When the proportion of LuPc$_2$ was high (10:1), the isotherms were compatible with a total miscibility of the two components. The calculated limiting area of 90 Å$^2$ was in agreement with the limiting area previously reported for LuPc$_2$ and corresponds to an edge-on orientation with the Pc ring perpendicular to the water subphase [28–30]. When DODAB was the majority component (1:10), the $\pi$-A isotherms showed a classical pattern of immiscibility consisting of two regions of different slope. At low pressures, the slope of the curve was 127 Å$^2$ coinciding with the limiting area registered for neat DODAB [31], whereas in the second steep rise of the surface pressure, the limiting area calculated was 90 Å$^2$ that coincided with the value of neat LuPc$_2$. The $\pi$-A isotherm of the equimolar mixture LuPc$_2$:DODAB (1:1), was consistent with a miscible system and showed a large area per molecule of 240 Å$^2$. This expansion of the monolayer could be due to repulsive interactions between LuPc$_2$ and DODAB or change of molecular accommodation at the surface [32].

SAuNPs were inserted in the LuPc$_2$:DODAB floating films by injecting the nanoparticles underneath the air–water interface. The insertion of the gold nanoparticles in the floating films was confirmed by the expansion of the area per molecule that increased with the amount of SAuNPs injected under the surface (Fig. 2, bottom). The expansion of the monolayer was clear in LuPc$_2$:DODAB mixtures 10:1 and 1:1. In contrast, in 1:10 films (low concentration of LuPc$_2$), the insertion of SAuNP was almost negligible suggesting that the insertion of the SAuNP was mainly due to the conjugation of SAuNPs to the phthalocyanine molecules. It is also important to indicate that injecting amounts of SAuNPs higher than 500 µL caused irreproducibility, probably due to the occurrence of phase segregation.

The quality of the floating films was further analysed using Brewster Angle Microscopy (BAM). In the absence of SAuNP, Langmuir films showed highly homogeneous surfaces. Films containing SAuNP showed a granular structure as a result of the insertion of the nanoparticles in the floating film. This is illustrated in Fig. 3 where the BAM images of LuPc$_2$:DODAB and LuPc$_2$:DODAB/SAuNP films are compared.

3.2. Electrochemical characterisation

The excitation power on the sample surface was kept below 100 kW cm$^{-2}$.

The electrochemistry was carried out in an EG&G PARC 273 potentiostat/galvanostat using a conventional three-electrode cell. The LB films were used as working electrodes. The reference electrode was Ag/AgCl/KCl 3 M, and the counter electrode was a platinum plate.

![Fig. 3. BAM images of (a) LuPc$_2$:DODAB (1:1) and (b) LuPc$_2$:DODAB/SAuNP (1:1/100).](image)
3.2. Langmuir–Blodgett films

3.2.1. Characterisation

The Langmuir films were transferred to solid substrates. The structure of the films deposited on a copper grid coated with carbon film was examined using TEM (Fig. 4). TEM images showed domains at micrometre scale formed by LuPc2:DODAB. The gold cores of the nanoparticles were observed as bright spots of 3.5–5.0 nm that coincided well with the core diameter of the SAuNPs used in this work. The SAuNPs were homogeneously distributed on the surface and were preferentially distributed in the border between LuPc2:DODAB domains.

The UV–vis absorption spectra of the LuPc2:DODAB films deposited onto quartz substrates were characterised by a Q band at 665 nm and a Soret band at 340 nm produced by π–π* transitions of the phthalocyanine ring (Fig. 5). These values were in good accordance with the results reported for LuPc2 and arachidic acid mixtures [28].

The intensity of the bands increased with the proportion of LuPc2 (1:10 > 1:1 > 10:1), in accordance with the Lambert–Beer’s Law. The increase in the LuPc2 proportion also caused a shift of the Q band to higher wavelengths (660 nm for the mixture 1:10; 665 nm for 1:1 and 675 nm for 10:1) indicating a higher level of aggregation and an extension of the aromaticity. The presence of J-aggregates in head-to-tail arrangement of transition dipoles in the LB film is responsible for this effect [33]. When inserting SAuNP particles in the structures, the Q and Soret bands increased their intensity. This enhancement was proportional to the amount of SAuNP introduced in the films, suggesting that the amplification was caused by the interaction between the phthalocyanine and the gold nanoparticles (the plasmon resonance of the SAuNP overlaps with the Q band of the LuPc2 [34]). In addition, the magnification caused by the SAuNPs increased proportionally with the proportion of DODAB used. This fact could be explained taking into account that DODAB decreases the degree of aggregation of the tightly packed phthalocyanine molecules, facilitating the interaction between LuPc2 and the SAuNP.

The LB films were investigated using micro-Raman technique, which combines morphological and chemical information at micrometre scale by coupling an optical microscope to a Raman spectrometer. Raman spectra registered with the 633 nm line are illustrated in Fig. 6. Since the LuPc2 absorbs the 633 nm laser line used here, the resonance Raman scattering (RRS) should take place [35].

![Fig. 4. TEM images of the LuPc2:DODAB/SAuNP (1:1/100).](image)

![Fig. 5. UV–vis spectra of 20 monolayers LB films of LuPc2:DODAB (1:1) (light grey); LuPc2:DODAB/SAuNP (1:1/100) (dark grey) and LuPc2:DODAB/SAuNP (1:1/500) (black).](image)

![Fig. 6. Resonant Raman spectra registered using the 633 nm laser line: Top: 3D line Raman mapping for a 10 monolayers LB film of LuPc2:DODAB/SAuNP (1:1/100). Down: Raman spectra collected from LuPc2:DODAB (1:1) (light grey); LuPc2:DODAB/SAuNP (1:1/100) (dark grey) and LuPc2:DODAB/SAuNP (1:1/500) (black).](image)
The RRS displays the well-known peaks corresponding to the active vibration modes of the LuPc$_2$ where the bands in the resonance region are clearly enhanced. For this reason, the spectra are dominated by four intense bands at 676 cm$^{-1}$, 737 cm$^{-1}$, 775 cm$^{-1}$ and 813 cm$^{-1}$ (associated with the Pc ring), whereas, the bands at higher wavelengths (associated with the pyrrole stretching at 1300–1500 cm$^{-1}$) are very weak. In contrast, when using the 532 nm laser line, the bands in the 1300–1600 cm$^{-1}$ region associated with the pyrrole are clearly observed [36].

The Raman spectra given in Fig. 6 (top) was obtained point-by-point for a line of 100 μm with step of 1 μm forming a line mapping. These RRS spectra revealed that the films were highly homogeneous with a regular distribution of the phthalocyanine molecules. However, as observed in Fig. 6 (down) the surface-enhanced resonance Raman phenomenon (SERRS) [37] was not clearly observed, and the presence of SAuNP only caused an increase in the fluorescence. The reason of this observation can be attributed to the small size and to the functionalization of the AuNPs. It has been demonstrated that the surface plasmon resonance of small AuNPs is dampened when compared to larger particles [34,38]. In addition, the distance dependence of the SERRS effect with the distance nanoparticle–molecule could also be the reason could be the small size of the SAuNP [37].

3.3. Electrochemical characterisation

Cyclic voltammetry of indium tin oxide (ITO) electrodes modified with Langmuir–Blodgett films of LuPc$_2$:DODAB immersed in 0.1 mol L$^{-1}$ KCl (at a scan rate of 0.1 V s$^{-1}$) showed a quasi-reversible process with the anodic peak at ca. 0.7 V and the cathodic peak at ca. 0.5 V. These peaks were due to the oxidation/reduction of the phthalocyanine ring (LuPc$_2$/LuPc$_2^+$) and their intensity increased with the proportion of LuPc$_2$ [39].

The insertion of SAuNP reduced the overpotential, causing a shift of the oxidation peak to lower potential values while increasing the intensity. This is illustrated in Fig. 7a and b where the voltammograms obtained from LuPc$_2$:DODAB (10:1) and a LuPc$_2$: DODAB/SAuNPs (10:1:500) at different scan rates (from 10 to 1000 mV s$^{-1}$) are presented. For instance, at a scan rate of 1000 mV s$^{-1}$, the peak that appeared at 0.9 V in LuPc$_2$:DODAB moved to 0.77 V in LuPc$_2$:DODAB/SAuNP (10:1:500) while the intensity increased from 460 μA to 920 μA.

In all the LB films studied (using different proportions of LuPc$_2$: DODAB and containing or not SAuNPs), a linear relationship was found between the peak current and the square root of scan rate ($v^{1/2}$) in the range from 10 to 1000 mV s$^{-1}$ indicating a diffusion limited process (Fig. 7c and d). In all cases, regression coefficients were higher than 0.994 for the oxidation peaks and higher than 0.987 for the reduction peaks.

It is worth noting that the curves were steeper for the films containing SAuNPs. For instance, the slope of the curve of the LuPc$_2$:DODAB (1:1) was 10.5, and the slope found in LuPc$_2$:DODAB/SAuNP (1:1:500) was 19.3. This means that the transfer process was two times faster in the presence of SAuNPs. This result proved that the mixed films containing both LuPc$_2$ and SAuNPs showed an excellent dynamic character in the redox process, and also that the charge transfer within the LB film and/or through the electrode interface was facilitated.

The oxidation and reduction of the Pc ring was counterbalanced by the diffusion of ions inside the LB films. Voltammograms carried out in electrolytes with common anions but different cations (i.e. in KCl and MgCl$_2$) were almost identical. In contrast, when changing the anion, important changes were observed. Experiments carried...
out in the presence of different electrolytes (Fig. 8) demonstrate that anions (instead of cations) diffused inside the films to maintain the electroneutrality. For this reason, voltammograms obtained in electrolytes containing a common anion were superimposable, whereas voltammograms obtained from solutions differing in the anion were different.

3.4. Electrocatatlytic properties

3.4.1. Voltammetric sensors

The electrocatalytic properties of the LuPc2:DODAB and LuPc2:DODAB/SAuNP LB films were tested towards hydroquinone. In order to avoid the polymerisation of the hydroquinone, experiments were carried out in the range from −0.5 to 0.7 V in buffer phosphate (PBS). Under these conditions, the oxidation of the phthalocyanines is no longer observed, and the redox processes registered, correspond to the oxidation/reduction of the hydroquinone. It has to be pointed out that the response registered when using a bare ITO electrode was extremely weak, and the peaks could not be clearly observed. As shown in Fig. 9 (top), LB films of LuPc2:DODAB 1:1 and 1:1.1 showed electrocatalytic activity for oxidation of hydroquinone, illustrated by a large increase in the intensity of the peaks associated with the oxidation/reduction of the antioxidant and a shift of the anodic peak to lower potentials (that appear at ca. 0.4 V). Films containing low concentrations of the bisphthalocyanine LuPc2:DODAB (1:10) displayed a weak response similar to that observed when using a bare ITO electrode. For this reason, the LuPc2:DODAB (1:10) films were not included in further studies.

Taken into account that the electrocatalytic activity was clearly enhanced by increasing the proportion of LuPc2 in the films, such behaviour can be attributed to the interaction of the hydroquinone with LuPc2 [40].

The presence of SAuNPs was found to increase the electrocatalytic efficiency of the sensors towards oxidation of hydroquinone. This increase was proportional to the concentration of SAuNPs (Fig. 9, down). For instance, the electrocatalytic efficiency of the films was increased by 5% for LuPc2:DODAB/SAuNPs (1:1/100) and 10% for LuPc2:DODAB/SAuNPs (1:1/500) (based on the current intensity of LuPc2:DODAB measured at 0.4 V).

The presence of SAuNPs increased the intensity of the oxidation current by creating active sites and improving the communication within the phthalocyanine films and the electrode. Similar electrocatalytic effects have been observed in electrodes covered with metallic nanoparticles and other organic materials [41,42].

As shown in the previous paragraphs, the peak-to-peak separation and electron transfer kinetics of LuPc2:DODAB/SAuNP modified electrodes changed with the amount of SAuNP inserted in the LB structure. However, it is important to notice that an excess of SAuNP (injecting more than 500 μL of SAuNP under the water subphase) did not produce further improvement leading to a decrease in electrochemical sensitivity and irreproducibility.

The peak current (measured at the voltage of oxidation or reduction of hydroquinone) showed a root square dependence with the scan rate (from 10 to 1000 mV s⁻¹) which indicates diffusion controlled mechanism for the oxidation/reduction of the species in solution. As shown in Table 2 that collects the data corresponding to the anodic waves, the presence of SAuNPs

increased the slope of the curve pointing to a favoured charge transfer process. The increase varied between 15% and 22% depending on the sensor.

The intensity of the peaks associated with the phenol increased linearly with the concentration of hydroquinone in the range from 5 μmol L⁻¹ to 150 μmol L⁻¹ (Fig. 10). The calibration curves were constructed by representing the intensity value of the anodic (ca. 0.45 V) and cathodic (at ca. −0.1 V) waves vs. the hydroquinone concentration. The limits of detection (LOD) were obtained according to the 3sₘ m⁻¹ criterion, where m is the slope of the calibration curve, and sₘ was estimated as the standard deviation (seven repetitions) of the voltammetric signal registered using the blank. The LOD calculated for all the sensors prepared are collected in Table 3. The improvement of the sensitivity caused by the synergistic electrocatalytic effect allowed the LuPc₂:DODAB/SAuNP sensors to reach limits of detection in the range of 10⁻⁶–10⁻⁷ mol L⁻¹ which are lower than those obtained for the corresponding LuPc₂:DODAB electrodes. These results demonstrate that the LuPc₂:DODAB/SAuNP nanostructured sensors can be used to quantify the presence of hydroquinone in the range usually present in foods and even below.

The responses were highly reproducible with a coefficient of variation (n = 10) lower than 2.0% between similar sensors (same composition). The reproducibility intra-assay was lower than 1.0%.

### 4. Conclusions

In this article, a method has been developed to prepare nanostructured electrodes of two electrocatalytic materials (functionalised AuNPs and lutetium bishthalocyanine) using the Langmuir–Blodgett technique.

The surface pressure–mean molecular area isotherms combined with BAM images indicate that SAuNPs are adsorbed into the floating films formed by LuPc₂ and DODAB. Spectroscopic and microscopic studies confirm that homogeneous LB films can be transferred to solid substrates.

Electrocatalytic properties of the LuPc₂:DODAB/SAuNP electrodes towards the detection of hydroquinone was evidenced by a decrease in the oxidation potential at which oxidation of hydroquinone takes place (peak appears at 0.8 V in bare electrode and at 0.45 V in modified electrodes). It was demonstrated that the SAuNPs and LuPc₂ have a synergistic effect in terms of improving electrocatalysis for the detection of hydroquinone as confirmed by the enhancement of the oxidation peak current, (at 0.45 V) and the reduction peak current (at −0.01 V).

Voltammetric responses were proportional to the concentration of hydroquinone between 5 μmol L⁻¹ and 150 μmol L⁻¹, and the limit of detection was in the range of 10⁻⁶–10⁻⁷ mol L⁻¹ with good reproducibility.
