Supporting Information

ABSTRACT: The constitution, configuration, and flexibility of the core sugars of DNA molecules alter their function in diverse roles. Conformational itineraries of the ribofuranosides (*fs*) have long been known to finely determine rates of processing, yet we also know that, strikingly, semifunctional DNAs containing pyranosides (*ps*) or other configurations can be created, suggesting sufficient but incompletely understood plasticity. The multiple conformers involved in such processes are necessarily influenced by context and environment: solvent, hosts, ligands. Notably, however, to date the unbiased, “naked” conformers have not been experimentally determined. Here, the inherent conformational biases of DNA scaffold deoxyribosides in unsolvated and solvated forms have now been defined using gas-phase microwave and solution-phase NMR spectroscopies coupled with computational analyses and exploitation of critical differences between natural-abundance isotopologues. Serial determination of precise, individual spectra for conformers of these 25 isotopologues in alpha (α -D) and beta (β -D); pyrano (*p*) and furano (*f*) methyl 2-deoxy-D-ribosides gave not only unprecedented atomic-level resolution structures of associated conformers but also their quantitative populations. Together these experiments revealed that typical 2E and 3E conformations of the sugar found in complex DNA structures are not inherently populated. Moreover, while both OH-5' and OH-3' are constrained by intramolecular hydrogen bonding in the unnatural *af* scaffold, OH-3' is “born free” in the “naked” lowest lying energy conformer of natural βf . Consequently, upon solvation, unnatural *af* is strikingly less perturbable (retaining 2T_1 conformation *in vacuo* and water) than natural βf . Unnatural αp and βp ribosides also display low conformational perturbability. These first experimental data on inherent, unbiased conformers therefore suggest that it is the background of conformational flexibility of βf that may have led to its emergence out of multiple possibilities as the sugar scaffold for “life’s code” and suggest a mechanism by which the resulting freedom of OH-3' (and hence accessibility as a nucleophile) in βf may drive preferential processing and complex structure formation, such as replicative propagation of DNA from 5'-to-3'.

INTRODUCTION

Structural variability and flexibility of ribonucleic acids are not only apparent and immense in scope but also intimately linked to both the existence^{1–3} and emergence^{4,5} of biological function. Moreover, ever-expanding interest in the design and use of both natural and unnatural ribonucleotides in diagnostic and therapeutic applications continues to highlight a key role for an understanding of the fundamentals that generate associated structural populations.^{6–8} For example, while chemical modifications at phosphate⁹ or nucleobase¹⁰ can usefully increase *in vivo* stability (reduced reactivity), it is also the correct manipulation of the conformations of the core sugar scaffold that has proven key to optimal functional activity. In DNA polymerases, an essential factor that prevents improper inclusion and extension of nucleotides appears to be governed by the preferred conformations of the furanose moiety of each incoming nucleotide during both incorporation

and extension.^{11,12} Interestingly, as the pioneering work of Eschenmoser¹³ highlighted, there is also no necessity for ribosidic or even furanosidic structures, and alternative polynucleotides can be constructed based on, for example, L-threo-furanosides¹⁴ or even configurationally varied pyranosides.¹³ While their functions are typically moderated (e.g., reduced base-pairing strengths), such altered-sugar polynucleotides can still adopt relevant duplex structures via typical (e.g., Watson–Crick) patterns and can even be processed by appropriate variant enzymes, albeit at reduced rates.

Figure 1. Coherent conformational analyses and comparison of DNA-scaffold ribosugars. (a) Schematic representation of the structure of dominant B-form DNA. (b) Compounds studied in this work: two 2-deoxyribofuranose forms (compounds *af* and *bf*) and two corresponding pyranose forms (derivatives *ap* and *bp*). (c) Overview of the precise, comparative protocol used in this work to determine D-ribosides in the gas phase (upper panel) and in aqueous solution (lower panel).

Together, such examples illustrate that both the fuller understanding of natural nucleotide function and the development of useful unnatural nucleotides require a deep insight into associated conformational preferences and, in particular, those of the native sugar moiety, 2-deoxy-D-ribose. However, no furanoside structures to date have been determined under fully isolated (and hence artefact free) conditions. Crystallographic data can be biased by both solvent effects and crystal-packing interactions. Spectroscopy in the solution phase is similarly dominated by environmental contacts.¹⁵ Indeed, extensive analyses performed on nucleosides and nucleotides, as well as in DNA, suggest that the sugar cores of such structures often exist in a dynamic equilibria between multiple conformations in solution.¹⁶

Here we present a strategy for the complete structural analysis of the core sugar scaffold of DNA, 2-deoxy-D-ribose (Figure 1a,b), that exploits custom-made, high-resolution microwave spectrometers combined with complementary vaporization and sampling techniques in the gas phase. Importantly, while associated quantum chemistry methods have been integral to prior analyses/interpretations of most gas phase structures, these microwave methods do not require quantum chemical computations during structural determination. Instead, natural abundance isotopologues act as key

structural references to allow atomic-level resolution. The resulting structures are therefore critically independent of the quality or processes of any associated quantum mechanical models. Comparison of these first unbiased conformational analyses with those affected by solution was then achieved by combining NMR experiments with experiment-guided molecular dynamics (MD) simulations (Figure 1c). This allows precise study of the inherent intramolecular interactions responsible for the structural diversity found in the core of DNA without interference from surrounding molecules in condensed media (e.g., water as solvent).

RESULTS

Design of a System for Generating and Analyzing Gaseous, Isolated DNA Scaffolds. Current understanding of DNA structure is based in significant part on X-ray crystallography data,^{17–20} providing information concerning global helical structure and the geometry of local features, such as base-pair stacking patterns and backbone conformation driven by that structure. However, such data can not only be biased by both solvent effects and crystal-packing interactions; it also provides only static structures. Conformational analyses of DNA fragments in solution can overcome some of these problems.²¹ However, the lack of sequence variety (dominated

Figure 2. High-resolution rotational spectra of αf , βf , αp , and βp . (a and b) Overview of the CP-FTMW rotational spectra of α and β deoxyribose anomers αf , βf in the 6–18 GHz region, respectively. In b, an expanded view highlights rotational transitions of each of the β -conformers. (c and d) Typical rotational transitions of αp and βp were observed using FTMW spectroscopy equipped with a UV ultrafast laser vaporization system. Rotational transitions showed hyperfine splitting due to internal rotation of the methyl group. Both transitions (c and d) are additionally split by the instrumental Doppler effect.

in general by A-tracts and the Drew–Dickerson dodecamer) combined with limitations in refinement protocols (sometimes biased by the quality of calculations used to interpret experimentally derived restraints²²) has not yet delivered a data set of structures with consistent information on the intrinsic mechanics of DNA in solution.²³ For instance, in some structures, significant deviations are seen from similar NMR data when refined with different backbone restraints,^{24,25} and in most studies conformational analyses rely on highly variable two-state models.^{26,27} Consequently, to date, no precise (atomic resolution) structures of DNA nor the biases of its scaffold have yet been reported.

In previous pioneering studies, conformational analyses of smaller carbohydrates fragments were accomplished using gas phase vibrational laser spectroscopy.^{28–31} However, these studies typically demand the use of molecules tagged with a chromophore that can be a potential cause of undesirable artefacts. While these can be replaced by external probes (e.g., toluene^{32,33} or peptides³⁴), this alternative methodology does not fully remove the need for chromophore and can induce additional unwanted environmental interference. Moreover, the method is critically dependent on quantum mechanical (QM) models to relate determined spectra to derived structures.

In this context, gas phase rotational spectroscopy emerges as a unique method that can avoid such artifacts. In particular, observation of multiple rotational spectra from isotopologues (e.g., where ¹³C replaces ¹²C) allows direct structural determination without dependence on QM models or chromophores. In addition, it possesses a superior inherent

resolution due to unsurpassed frequency resolution (\sim kHz) and unrivalled chemical (conformers, tautomers, isotopologues, even enantiomers) discrimination.^{35,36} However, the ability to measure isotopic species directly requires sufficient sensitivity (or enriched samples), which in turn demands sufficient partial pressure of the analyte in the gas phase. For analytes, such as carbohydrates, that have low volatility and are thermolabile, this has proven challenging using traditional heating methods³⁷ or even IR nanosecond-pulsed laser vaporization techniques.³⁸ Recently, we have shown that UV (355 nm) picosecond-pulsed (\sim 40 ps) laser vaporization can allow observations of certain reducing sugars,^{39–42} but their mutarotation^{39,40} and/or lack of sensitivity^{39,41} prevented either observation of biologically relevant constitutional forms or structures with atomic resolution; consequently, observation of core DNA scaffold 2-deoxy-D-ribosides (Figure 1b) was not previously possible.

We reasoned that the required critical increase in sensitivity might be gained in several ways. This proved successful through the custom design (Supplementary Figures 1 and 2) of microwave apparatus that included a Fourier-transform microwave-spectrometer (FTMW)⁴³ coupled to a UV ultrafast laser vaporization system³⁹ and a set-up with chirped-pulses (CP-FTMW) (Figure 1c).⁴⁴ Specifically, the latter system allowed: (a) simultaneous three-nozzle gas injection; (b) longer acquisition times (allowing even spectral registration for 1 week continuously averaging \sim 40 million of rotational spectra); and (c) more efficient radiation pulse sequences (30 microwave pulses per molecular pulse). These features together provided an increase of an order of magnitude (or

greater) sensitivity, which in turn allowed lower consumption of the sample (down to 0.7–2.0 g of synthetic samples). In this way, even each of the multiple isotopologues present in samples at only natural abundance ($^{13}\text{C}^{12}\text{C}_5\text{H}_{12}\text{O}_4 \approx 1.1\%$) could be detected and characterized. These advances allowed us to determine, for the first time, “nonbiased” atomic resolution structures of core DNA scaffold 2-deoxy-D-ribosides.

Experimental Determination of Unbiased Structures of DNA Scaffold Sugars. First, core putative scaffolds αf , βf , αp , and βp (Figure 1b) were readily synthesized by complementary methods on the multigram scales required. Briefly (see [Supplementary Methods](#) for further details), in one method 2-deoxy-D-ribose was subjected to classical Fischer glycosylation conditions (1% HCl in methanol); the equilibrium mixture after 18 h (57% βp , 15% αp , 11% βf , 17% αf) yielded αp by column chromatography and βp by further crystallization. To generate αf and βf on scale, we preferentially employed brief (15 min) treatment, giving an $\sim 1:1$ mixture of essentially only furanosides; subsequent

peracetylation/deacetylation allowed clean isolation via column chromatography (33% βf , 36% αf).

Next, gas-phase DNA scaffold generation was tested under various modes (Figures 1c and 2). Of these, CP-FTMW spectroscopy allowed collection of rotational spectra of αf and βf . (Figure 2, panels a and b, respectively). An FTMW spectrometer coupled to UV ultrafast laser vaporization proved most successful for αp and βp . Together, these experiments allowed long acquisition times from gram-scale samples thereby yielding rotational spectra of the “nonbiased” structures of αf , βf , αp , and βp with an unprecedented signal-to-noise ratio (S/N for most intense observed transitions: $>500/1$ and $>1800/1$ for αf and βf , respectively). In turn, such S/N orders allowed determination of structures with atomic resolution. In this way, despite heavily congested spectra— αf (Figure 2a) and βf (Figure 2b) showed ~ 600 and ~ 1800 rotational lines, respectively—sets of rotational transitions were identified belonging to independent structures.

Each transition set was fitted to a semirigid rotor Hamiltonian based on Watson's symmetric reduction and I' representation to obtain A , B , and C rotational constants and critical centrifugal distortion constants.^{45,46} Conformational assignments were guided and supported by (but not dependent on, *vide infra*) theoretical calculations, using a two-step MM then QM (DFT and *ab initio*) strategy^{39,42} (see [Supplementary Methods](#)). Rotational constants can be correlated with moments of inertia, which are a fingerprint of 3D molecular structure (Table 1). Direct comparison of simulated and experimental rotational constants (Table 1 and [Supplementary Tables 1, 3, 5, and 6](#)) therefore allowed an unequivocal assignment.

Two *af* conformers (named *af*-1 and *af*-2, numbered by calculated energy ranking, Figure 2a) and three different *βf* conformers (*βf*-1, *βf*-5, and *βf*-6, Figure 2b) were identified, whereas for *ap* and *βp* only single (dominant) conformers (Figure 2c,d) were detected (Table 1 and [Supplementary Tables 1, 3, 5, and 6](#)). Other low energy conformers as *βf*-2 or *βf*-3 were not detected, likely due to relaxation to the most stable *βf*-1 through interconversion pathways (see [Supplementary Figures 3 and 4](#)). Notably, in both *ap* and *βp*, even hyperfine-splitting due to internal rotation of the methyl group could be observed and analyzed (Figure 2c,d). The resulting experimental spectroscopic parameters and experimental frequencies provide an extensive "structural map" of all possible 2-deoxy-ribose sugar scaffolds ([Supporting Information](#)).

Notably, such was the sensitivity that it allowed detection of ¹³C isotopes in natural abundance (~1.1%). Strikingly, we were able to observe the rotational spectra for all (18 additional ¹³C¹²C₅H₁₂O₄ species) of the monosubstituted ¹³C isotopologues distributed within this small abundance for the most populated conformers *af*-1, *βf*-1, and *ap*-1. As noted, correlation of moments of inertia with rotational constants renders them a key source for structural information. Moments of inertia depend critically on distribution of atomic masses, and so molecular geometry, and are affected by vibrational energy even in the ground state, since molecules are not rigid systems. Except for simplified cases, the explicit correction of the moments of inertia for vibrational contributions has not been possible because of related experimental difficulties. Therefore, different procedures and/or evaluations of molecular structures were tested, all exploiting isotopologue spectra (Figure 3b). *Equilibrium structures* (r_e , Figure 3b) represent the hypothetical vibration-less state that corresponds to the minimum of the potential energy surface. This structure, essentially inaccessible to molecules, is the one obtained by typical computational methods. *Effective structures* (r_0 , Figure 3b)⁴⁷ reproduce rotational constants in the ground state and were derived here starting from the calculated geometry and through iterative least-squares adjustments of experimental rotational constants of each deoxyribose (21 = 3 for parent + 6 × 3 for isotopologues). *Substitution structures* (r_s , Figure 3b),^{48,49} obtained from the analysis of the changes of the moments of inertia resulting from a single isotopic substitution, allow determination of the atomic coordinates of the substituted atom. This " r_s method" has the advantage that it provides the position of the substituted atom free from other assumptions about molecular structure and so does not depend on computational calculations. Such r_s structures are generally assumed to be intermediate between r_0 and r_e .⁴⁵ For these reasons, such "real" experimental geometries (r_s and r_0) are not

directly comparable with those obtained by typical computational methods (r_e). In this way, the accuracy of rotational spectroscopy yielded riboside structures with unprecedented resolution (Figure 3b and [Supplementary Tables 8–13](#)).

Analysis of Gas-Phase Rotational Transitions of Core DNA Scaffolds Reveals Conformers and their Inherent Populations. Rotational spectroscopy allowed not only determination of unbiased, experimentally accurate structures but also an estimation of the population ratios between these different observed conformers by analyzing the relative intensities of associated rotational transitions.⁵⁰ *af* adopts preferably two conformers in the gas phase, *af*-1 (²T₁ *gg*, Figure 3) and *af*-2 (²T₁ *gt*), in a ratio *af*-1/*af*-2 of 80(20):20, whereas for *βf*, three different conformers were identified (Figure 3c): *βf*-1 (⁴E *gg*), *βf*-5 (E₂ *tg*), and *βf*-6 (¹T₂ *gt*) in a 93(10):4(1):3 population ratio. Only one conformer was detected for either *ap* (⁴C₁) and *βp* (¹C₄).

For *af*, both observed conformers (*af*-1 and *af*-2) share the same ring shape ²T₁, stabilized by two intramolecular hydrogen bonds: O3'–H3'...O1' and O5'–H5'...O4' across both α and β faces. On the other side, *βf*-1 (*gg*) adopts a partly distorted ⁴E conformation. This puckering is stabilized by a strong hydrogen bond O5'–H5'...O1', which is viable only when the C5'-hydroxymethyl group adopts a *gg* arrangement. Notably, a "switched" loss of this stabilizing interaction in *βf*-5 (*tg*) and *βf*-6 (*gt*) causes them to adopt somewhat distorted puckered ring E₂ and ¹T₂ conformations, respectively, similar to those found in methyl β -D-ribofuranoside.⁴¹

The pyranosides *ap* and *βp* were much more rigid in the gas phase, exhibiting single dominant conformers (Figure 3c). *ap* adopts a ⁴C₁ chair, while *βp* adopts the inverted ¹C₄. In both, reinforcing hydrogen bond networks on the α face, akin to reinforcing hydrogen bonding networks seen previously using IR spectroscopy in hexopyranosides,⁵¹ further drive this rigidity (for *ap*-1: O4'–H4'...O3'–H3'...O-1' and for *βp*-1: O3'–H3'...O4'–H4'...O5') beyond the known greater barriers to conformational interconversion found in pyranosides.

In all scaffolds, the orientation of the methyl group was in accordance with the *exo*-anomeric effect,^{34,52} with values of ϕ close to either 60° or –60° for the α - (*af*, *ap*) and β - (*βp*, *βf*) anomers, respectively. This serves to place the methyl group in a site of essentially low influence with regard to conformation. Strikingly, and in clear contrast to α -anomer *af* and both pyranosides *ap* and *βp*, only in *βf* was the hydroxyl O3'–H3' not engaged in hydrogen bonding—the lowest lying conformer of natural scaffold *βf* therefore uniquely frees OH-3', and hence the α -face remains consequentially more accessible (and potentially reactive, *vide infra*).

Comparison of Inherent Conformers of DNA scaffolds with Solvated Structures Reveals Selectively Driven Conformational Change for 2-deoxy- β -D-ribofuranoside *βf*. DNA functions in both aqueous and partly hydrated (e.g., enzyme active site) environments. To study the effect of the hydration state on the structure of these core scaffolds derivatives, *af*, *ap*, *βp*, and *βf* were subjected to conformational analysis in aqueous solution by combining NMR spectroscopy measurements (³J_{H,H} coupling constants as constraints) with molecular dynamics (MD) simulations. Calculations were performed in AMBER18,⁵³ implemented with the GLYCAM06 force field.⁵⁴ Notably, extended (5 μ s) MD simulations *alone* performed on derivatives *af* and *βf* grossly failed to reproduce experimental data ([Supplementary](#)

Figure 4. Conformational analysis of αf and βf in aqueous solution. (a) Structural ensembles derived from 0.2 μ s MD-tar simulations, together with the root-mean-square deviation (RMSD) values for the heavy atoms in both anomers and the average value of ϕ torsional angle through the entire MD-tar trajectory. (b) Distribution of torsional angle ω for αf and βf derived from MD-tar simulations in aqueous solution. (c) Water oxygen density for the first hydration shell derived from experiment-guided MD simulations for αf and βf . The average structure of the carbohydrate is represented. (d) Cremer–Pople diagrams for αf and βf derived from experiment-guided MD simulations. N, S, E, and W stand for “North”, “South”, “East”, and “West” forms. The dark blue circles represent the conformations found in the gas phase. The red circles denote the conformation found in DNA. Finally, the light blue circles show the conformations found in the gas phase for methyl β -D-ribofuranoside.⁴¹ The contour coloring indicates the population (in arbitrary units) of the different conformers obtained from experiment-guided MD simulations.

Table 15), predicting a rather flexible five-membered ring with almost free pseudorotation (Supplementary Figures 5 and 6). However, MD simulations (0.2 μ s) using experimental $^3J_{\text{H,H}}$ constants as time-averaged restraints (MD-tar simulations,⁵⁵ exploiting additional restraining potential terms added to the force field) successfully predicted ensembles of low-energy conformers that quantitatively reproduced NMR data (see Figure 4 and also Supplementary Tables 14 and 15 for $^3J_{\text{H,H}}$ constants).

These simulations revealed that in the furanosides αf and βf the C-5' hydroxymethyl group is notably flexible in water (Figure 4b) and preferentially adopts gg and gt staggered rotamers for both. Of note, no significant intramolecular hydrogen bonds were detected in solution, with a population <10% in all cases. Analysis of the first hydration shell predicts that αf can accommodate more water molecules than βf (19 versus 15, Figure 4c). Together these solvent interactions drive scaffold-specific conformer selection from corresponding “naked” cores. Thus, while unnatural scaffold αf populates 2T_1 and 2E conformations (Figure 4d) in both gas and solution phase (“unselected”), the natural scaffold βf is driven from 4E in the gas phase βf -1 to E_2 and 3T_2 by the loss of intramolecular bond $\text{O}5'-\text{H}5'\cdots\text{O}1'$ enabled by the observed flexibility of the C-5' hydroxymethyl group, in agreement with conformers derived by fitting the experimental homo- and heteronuclear 3J coupling constants to a two-state model^{56,57} (2E and 3T_2 for αf and βf , respectively).

For the pyranosides αp and βp , characteristic $^3J_{\text{H}_2\text{a,H}_3}$ values confirmed strong propensity to remain in chair conformations⁵⁸ observed in the gas phase, yet with inverted conformation ($^4C_1 \rightarrow ^1C_4$ and $^1C_4 \rightarrow ^4C_1$, respectively). This result is also in line with previous studies.⁵⁹ In contrast to the furanosides, unrestrained MD simulations gave good

agreement with experiment (Supplementary Table 16); extended analyses of total trajectory time (Supplementary Figures 7 and 8) suggested that αp is driven in solution to adopt only a 82(5)% partial 1C_4 -to- 4C_1 equilibrium position. As expected, no significant intramolecular hydrogen bonds (population of <10%) were detected in solution through the MD simulations for either of the anomers. On the other hand, full solvation analysis performed by MD revealed that the conformational inversions are driven by an ability to properly accommodate the water in its first hydration shell, which more than offsets *endo*-anomeric preferences. Moreover, in the case of the α -anomer, the 1C_4 conformer features a larger dipole moment relative to the 4C_1 chair, which could also explain why this anomer preferentially adopts the 1C_4 chair in aqueous solution.

DISCUSSION

There are considered to be three broad conformational determinants in DNA residues: C4'–C5' rotation (i.e., *g/t*); base position/“flip” (i.e., *syn/anti*); and ring pucker (i.e., “North”/“South”) pseudorotation (Figure 4d). Although to some extent linked, sometimes even mutually “geared”⁶⁰ and accessible via typically relatively low barriers, it is the latter from these that appears to dominate function. In general terms, therefore many biomolecular interactions with such “DNA sugar scaffolds” are found to favor function with either North or South sugar ring conformers.

A North-vs-South (N-vs-S) delineation is an observation made well beyond the more obvious and static structures, such as in for example A- or B-form duplex DNA. Thus, through the use of structural biology, spectroscopy, and elegant probe molecules (e.g., conformationally restricted variants^{26,61,62}), a clear role for the conformation of deoxynucleosides in

determining their biological function has emerged in recent decades.⁶³ For example, clear “N-vs-S” preferences have been seen in the function of base deaminases,⁶⁴ base C-methyltransferases,⁶⁰ kinases,⁶⁵ and even receptors⁶⁶ and transporters.⁶⁷ This can have profound effects; DNA-polymerizing enzymes, such as reverse transcriptase⁶⁸ or polymerases,⁶⁹ can have striking apparent selectivity; AZT, for example, is bound in essentially an exclusively North form by HIV reverse transcriptase, and this conformational mimicry appears critical to its potency.⁶⁸

As a result, the delineation in this work of the inherent preferences of the available ribosides αf , αp , βp , βf and their behavior upon hydration allows consideration of the fundamental biases of such scaffolds. Notably, it is the natural scaffold βf that displays a unique “tipping point”/“knife-edge” conformational behavior that allows the greatest malleability by environment. Here, we observe population of kinetically trapped Southern (βf -1) and Northern conformers (βf -5, βf -6) as well as the “tipping” by water of βf -1 into “Northern” conformers. Associated assumptions have often been made around the central role of “sugar pucker”. For example, the itinerary of the equilibrium between North and South has always been assumed to proceed “via the East”.⁶² Yet, here we see that βf sits in a semi-Western (indeed, SW tending to W) ⁴E βf -1 pucker as its baseline conformer. Any engagement by “naked” βf -1 with the environment (e.g., added solvent or biomolecule) therefore starts from this point.

The partial population of clear Northern conformers βf -5 and βf -6 even when “naked” also suggests that βf is conformationally “primed”. The unnatural deoxyribose scaffold variants αp , βp , and even αf do not show this behavior. The switched loss of strength of the OS′–HS′... aglycone hydrogen bond seen here (either through hydration, protein binding, or covalent capping, e.g., as OS′-P phosphoester) thus precludes the occurrence of this pucker leading to the adoption, in turn, of Northern (i.e., E₂ or ¹T₂ structures upon hydration) highly similar to those of βf -5 and βf -6. In this way, βf is therefore uniquely suitable for a switchable (e.g., South-to-North) transition, unlike all of the other scaffolds studied here—it is “ready to switch”. Notably, the C2′ hydroxylated scaffold of βf (the RNA scaffold equivalent of βf) is already tipped to North (³T₂), further highlighting the uniqueness of the βf 2-deoxyribose scaffold.

Notably, in βf the OH3′ hydroxyl group is not engaged in a hydrogen bond in the lowest lying energy conformer (βf -1, as well as in fact βf -6) found in the gas phase; βf -5 has interaction with OHS′ but contributes only 4% to the global population. Together, these combined factors (“tipping point” conformation and exposed OH3′) allow us to speculate further on the functional benefit of the βf scaffold over others. N ↔ S conformational transition allows strong modulation of the OS′-to-O3′ distance; a switchable system with OH3′ exposed at modulated distances for the reaction would allow a mechanism for ready positional alteration and hence the semiexpulsion of ligand that is thought to be critical for reducing product inhibition (and hence allowing more efficient turnover) in processive enzymes such as nucleotidyl polymerases and reverse transcriptases.⁷⁰ In other words, the ready positional manipulation of a “free OH3′” uniquely in the βf scaffold is potentially beneficial in many biocatalytic (and hence functional) scenarios. More generally, it might even explain the observed direction of such polymerizations of DNA in nature in growing from 5′-to-3′ (via such a modulated, free OH3′).

This may not be restricted to polymerases given the wide N-vs-S preferences noted above. In several nucleoside/tide kinases, which operate at the OS′-site of ribosides, a critical and evolutionarily conserved role has been identified for OH3′: hydrogen bonding to homologous Tyr-Glu diad motifs is required in several to ensure catalysis.⁷¹

It is also tempting to speculate that, given the context of DNA polymerases as archetypal models for elegant but sometimes nonaligned “induced fit” hypotheses (for an excellent comparative discussion see ref 72), this may be part of broader conformational, “prechemistry” mechanisms—potential triggers for induced fit.

Regardless, it is clear that the unique flexibility that we observe for “naked” βf for the first time is striking and likely an important determinant in its utilization/selection by nature as a scaffold from many stereo- and constitutional sugar isomers. Although such conformational “fitness” has been the subject of insightful prior speculation,⁷³ our work provides the first direct experiment of such a flexible trigger based on inherent conformational tendencies in the βf scaffold.

Finally, given the low barriers for DNA conformational interchange and the discrepancies that we observed in the work presented here exploiting existing QM and MM methods, the structures we present here (nonreliant on QM) should prove valuable in benchmarking future quantum mechanical models. In this way, our combined approach opens up the exploration of DNA’s mechanistic tendencies to even larger systems in the future.

METHODS

Synthesis. The 2-deoxyribosides αf , βf , αp , and βp (Figure 1) were synthesized by modification of a previously published literature procedure.⁷⁴ Briefly, for access to αp and βp , 2-deoxy-D-ribose was dissolved in 1% HCl in methanol and stirred for 18 h. After the reaction workup, pure αp was obtained through purification by column chromatography. The remaining 2-deoxyribosides βp , αf , and βf coeluted as an inseparable mixture, but recrystallization of this mixture in diethyl ether afforded pure βp . For access to αf and βf , 2-deoxy-D-ribose was dissolved in 0.1% HCl in methanol and stirred for 15 min. After the reaction workup, the mixture of αf and βf was acetylated using acetic anhydride in pyridine and pure αf -2OAc and βf -2OAc was obtained through purification by column chromatography. Deacetylation using K₂CO₃ in methanol yielded pure αf and βf . Full experimental details can be found in the Supporting Information.

Pulse Fourier Transform Microwave Spectrometers. To obtain the rotational spectra of the furanose species, we used a chirped-pulse Fourier transform microwave spectrometer (CP-FTMW) built at the Spectroscopy Group at the University of the Basque Country (UPV/EHU)⁴⁴ and following the design of Pate and co-workers (Supplementary Figure 1).⁷⁵ A short broadband pulse (1 μ s, 12 GHz, frequency range 6–18 GHz) is generated by an Arbitrary Waveform Generator (AWG) and amplified by a Traveling Wave Tube Amplifier (TWT). The pulse is broadcast into a high vacuum chamber (down to 10⁻⁶ mbar) through a Q-par horn antenna where it interacts with the molecular supersonic jet expansion. The time-domain signal of the molecular emission is collected by another horn antenna and delivered to a digital 20 GHz oscilloscope and Fourier-transformed to obtain the rotational spectrum in the frequency domain. The spectral resolution of this apparatus is ~10 kHz.

Rotational spectra of pyranose conformers were recorded in a 4–18 GHz Fourier transform microwave spectrometer (FTMW) based on the Balle-Flygare design,⁷⁶ constructed at the UPV/EHU and described elsewhere (Supplementary Figure 2).⁴³ Appropriate excitation pulses create optimum $\pi/2$ polarization conditions on the sample, which expands in a supersonic jet coaxially within a Fabry-Pérot microwave resonator. The resulting transient spontaneous emission from the expanding molecular ensemble is amplified and down-converted to the radio frequency region, where it is digitized, and Fourier transformed to yield the frequency-domain spectrum. All transitions recorded in this spectrometer appear split into two Doppler components, because of the coaxial arrangement of the molecular jet and the resonator. The higher spectral resolution of this apparatus (better than 5 kHz) allowed us to resolve the hyperfine line splittings due to internal rotation of methyl tops, where present.

Samples in the CP-FTMW spectrometer were vaporized by a conventional heating method by wrapping a heating wire to a customized nozzle at 145 °C. The vacuum chamber hosts three pulsed solenoid valves running simultaneously in order to increase the signal-to-noise ratio. Gaseous samples were mixed with He carrier gas at 6 bar, and the resulting flow was injected into the vacuum chamber through a small orifice (1 mm diameter), producing the gas expansion and subsequent cooling (rotational temperature near 5 K). The duration of the molecular pulse was 0.5–1.2 ms. Two nozzles were enough for αf , whereas three nozzles were used for βf , at 30 chirps per molecular pulse. To obtain a good signal-to-noise ratio, a total of 20 and 40 Mcycles were collected for the αf and βf spectra, respectively. In the FTMW spectrometer equipped with UV ultrafast laser vaporization,³⁹ it consists of a mixture of the chemical compound and a commercial binder, mechanically pressed to get cylinder-type solid rods that are inserted in the apparatus and rotated by a stepper motor. A picosecond pulse from the third harmonic (355 nm) of a Nd:YAG laser hits the rod in the presence of Ne carrier gas (~6 bar), delivering the molecules intact into the gas phase. This technique prevents sample decomposition, that often happens with biomolecules upon thermal heating.

Computational Details. Conformational Search. The conformational search used a molecular mechanics approach with MMFFs, OPLS, and AMBER force fields in a 20 kJ/mol energy window and was followed by geometry optimizations with quantum chemistry calculations [*ab initio* MP2 and DFT (B3LYP-D3)] with 6-311++G(d,p) basis functions. Gaussian 16 software⁷⁷ was used in all cases.

Unrestrained MD Simulations. Simulations were performed with the AMBER18 package,⁵³ implemented with a GLYCAM06⁵⁴ force field. Each molecule was immersed in a water box with a 10 Å buffer of TIP3P water molecules. A two-stage geometry optimization approach was performed. The first stage minimizes only the positions of solvent molecules, and the second stage is an unrestrained minimization of all the atoms in the simulation cell. The systems were then gently heated by incrementing the temperature from 0 to 300 K under a constant pressure of 1 atm and periodic boundary conditions. Harmonic restraints of 30 kcal mol⁻¹ were applied to the solute, and the Andersen temperature coupling scheme was used to control and equalize the temperature. The time step was kept at 1 fs during the heating stages, allowing potential inhomogeneities to self-adjust. Long-range electrostatic effects are modeled using the particle-mesh-Ewald

method.⁷⁸ An 8 Å cutoff was applied to Lennard-Jones interactions. Each system was equilibrated for 2 ns with a 2 fs time step at a constant volume and temperature of 300 K. Production trajectories were then run for an additional 5 μ s under the same simulation conditions.

Experiment-Guided MD Simulations. The setup of the MD simulations with time-averaged restraints was identical, in terms of force fields, water model, and algorithms to that described above for the unrestrained MD simulations. The experimental ${}^3J_{\text{H,H}}$ coupling constants were imposed as a time-averaged restraint, applying a linear averaging. The equilibrium 3J range was set to ${}^3J_{\text{exp}} - 0.2 \text{ Hz} \leq {}^3J_{\text{exp}} \leq {}^3J_{\text{exp}} + 0.2 \text{ Hz}$. Trajectories were run at 300 K, with a decay constant of 20 ns and a time step of 1 fs. The force constants rk_2 and rk_3 used in each case were 0.2 kcal mol⁻¹ Å⁻². The overall simulation length was 0.2 μ s. The theoretical 3J coupling constants were deduced from the dihedral values through the corresponding Altona equation and Sweet J software.^{58,79}

Analysis of the First Hydration Shell from the MD Simulations. The water density properties were derived from the production trajectories using a cubic grid consisting of 150 × 150 × 150 bins with 0.5-Å spacing, through the “grid” command available in the *cpptraj* module of AMBER18. The surfaces represented in Figures 4 and Supplementary Figure 7 correspond to oxygen water density for the first hydration shell.
